## Abstract

Snow cover is of key importance for water resources in high mountain Asia (HMA) and is expected to undergo extensive changes in a warming climate. Past studies have quantified snow cover changes with satellite products of relatively low spatial resolution (~500 m) which are hindered by the steep topography of this mountain region. We derive snowlines from Sentinel-2 and Landsat 5, 7 and 8 images, which, thanks to their higher spatial resolution, are less sensitive to the local topography. We calculate the snow line altitude (SLA) and its seasonality for all glacierized catchments of HMA and link these patterns to climate variables corrected for topographic biases. As such, the snowline changes provide a clear proxy for climatic changes. Our results highlight a strong spatial variability in mean SLA and in its seasonal changes, including across mountain chains and between the monsoon-dominated and the westerlies-dominated catchments. Over the period 1999–2019, the western regions of HMA (Pamir, Karakoram, Western Himalaya) have undergone increased snow coverage, expressed as seasonal SLA decrease, in spring and summer. This change is opposed to a widespread increase in SLA in autumn across the region, and especially the southeastern regions of HMA (Nyainqentanglha, Hengduan Shan, South–East Himalaya). Our results indicate that the diversity of seasonal snow dynamics across the region is controlled not by temperature or precipitation directly but by the timing and partitioning of solid precipitation. Decadal snowline changes (1999–2009 vs 2009–2019) seasonally precede temperature changes, suggesting that seasonal temperature changes in the Karakoram–Pamir and Eastern Nyainqentanglha regions may have responded to snow cover changes, rather than driving them.

## 1. Introduction

Mountain snowpacks are a key component of the water balance in the major river basins of high mountain Asia (HMA, e.g. Immerzeel *et al* 2020) and deliver seasonally-delayed discharge that is especially crucial in arid regions and drought years (Pritchard 2019). Snowpacks in the region are expected to be highly sensitive to future climate warming (Kraaijenbrink

*et al* 2021) with severe consequences for vulnerable ecosystems and communities downstream (Viviroli *et al* 2020). Snow cover changes are an important control of the land surface energy balance, and can feed-back to the climate system. For example, snow cover reduction is often associated with enhanced warming at high elevations through the snow-albedo feedback (e.g. Palazzi *et al* 2019), while changes in precipitation seasonality and phase can have a strong effect on

mass accumulation (e.g. Jouberton *et al* 2022). A general increase in precipitation and a general decrease in snow cover are expected at the scale of HMA in the coming century, with a high spatial variability and dependence on the socio-economic pathway (Lalande *et al* 2021). Consequently, the future climate response of snowpacks is not mechanistically linked to temperature alone, although temperature changes are clearly associated with changes in snow cover seasonality (Notarnicola 2020, Tang *et al* 2022). Understanding historic snowpack dynamics and climatic controls is therefore crucial to consider the future of high-mountain catchments and of the systems that depend on their water resources.

The extremely rugged topography of HMA, combined with spatially contrasting mesoscale atmospheric drivers, leads to a diversity of climates across the region associated with a diversity of glacier mass balance patterns (e.g. Maussion *et al* 2014, Mölg *et al* 2014, Sakai and Fujita 2017). Characterizing this diversity and its evolution is hindered by the relative lack of high-elevation measurements (Tang *et al* 2013, Immerzeel *et al* 2015, Matthews *et al* 2020, Miao *et al* 2024). Therefore, researchers have favored remote sensing assessments of snow dynamics, investigating snow cover patterns (Zhou *et al* 2013, Li *et al* 2019) and trends (Smith *et al* 2017, Ackroyd *et al* 2021, Tang *et al* 2022). However, these studies have relied on coarse satellite data (e.g. MODIS at 500 m resolution) that capture the broad seasonal and spatial changes but are affected by steep topography and cloud cover (e.g. Stillingner *et al* 2019) which inhibits their reflection of fine-scale processes such as radiation-driven snowmelt (e.g. Bouamri *et al* 2021). Estimates of snow depth (Lievens *et al* 2019) and snow–water equivalent (Smith and Bookhagen 2018) rely on even coarser satellite data and/or numerical models (e.g. Liu *et al* 2021) to estimate volumes or mass at kilometer- to basin-scales. These metrics, though, due to their integration of large observational areas, are difficult to compare between domains because they also integrate dissimilar distributions of elevation, area, and aspect. Snowlines are an alternative metric of snow dynamics at the catchment and basin scale which are independent of such hypsometric biases (Krajčič *et al* 2014, Xiao and Liang 2024) while reflecting the spatial variability of the meteorology (Tang *et al* 2014). As such, they provide a clear proxy for climatic changes (McFadden *et al* 2011, Hu *et al* 2019, Aranda *et al* 2023) and are sometimes employed for quantifying and modeling interannual changes in glacier health (e.g. Klein and Isacks 1999, Rabatel *et al* 2012, Mernild *et al* 2013, Spiess *et al* 2016, Barandun *et al* 2018, Racoviteanu *et al* 2019, Tang *et al* 2020, Loibl *et al* 2025). Snowlines are most often derived from snow cover maps from optical

satellite images at various spatial and temporal resolutions (Krajčič *et al* 2014, Xiao and Liang 2024). When derived from high-resolution data, they have proven useful for disentangling the meteorological drivers of seasonal snow cover change, including in catchments with steep topographies, with vertical uncertainties of the order of ~10 m (e.g. Girona-Mata *et al* 2019, Sasaki *et al* 2024). However this analysis has not previously been applied beyond individual catchments, and a comprehensive understanding of snow dynamics across HMA's varied water basins is missing.

In this study, we leverage the Google Earth Engine (GEE) archive of Landsat and Sentinel-2 high-resolution multispectral satellite images to measure snowline altitudes in all of HMA glacierized catchments, accounting for clouds, rock outcrops, glaciers, and surface water in each scene from 1999 to 2019. We use these measurements to construct a climatology of the snowline seasonal variations in each catchment across the region. We then disentangle the meteorological drivers of the variable snowline seasonality based on the ERA5-Land climate reanalysis, corrected for each catchment's hypsometric biases. Finally, we assess seasonal snowline changes between 1999–2009 and 2009–2019 and their relationship to meteorological forcings.

## 2. Methods

### 2.1. Catchment snowline altitudes

We derived snowlines for all glacierized catchments across HMA for the period 1999–2019. The catchments were defined as the intersection of the Randolph Glacier Inventory 6.0 (hereafter RGI; Pfeffer *et al* 2014) and the HydroBASINS (Lehner and Grill 2013) for the Central Asia, South Asia West, and South Asia East in RGI. We used the Pfafstetter level 9 polygons to delimit catchments of relatively similar size across the region. This resulted in 4776 glacierized catchments across the region, from 27° N to 47° N and from 66° E to 105° E (figure 1), which vary considerably in topographic distribution (SI figure 1). As all these catchments contained glaciers as of the RGI inventory date (early 2000s), we expected that they would all be affected by seasonal snow.

For each catchment we used publicly-available satellite multispectral data from 1999 to 2019 (top-of-atmosphere Sentinel-2 and Landsat 5, 7 and 8 scenes) to produce snow cover and snowline elevation time series in GEE. We filtered the scenes based on their metadata to only consider those with more than 50% cloud free area, and performed the following scene-by-scene analysis for each catchment, closely following the method developed by Girona-Mata *et al* (2019) and adapted for GEE by Sasaki *et al* (2024):

1. First, all clouds and shadows were masked within each scene to reduce false positive snow cover identification. For Landsat (30 m resolution) and Sentinel-2 (10 m resolution) sensors, we used the Quality Assessment bands which contain bitwise masks for clouds. For shadow mapping, with Landsat we adopted the approach of Miles *et al* (2017) based on the blue and near-infrared top-of-atmosphere reflectance values, using thresholds of 0.2 as in the original study. With Sentinel-2, we used the method by Hollstein *et al* (2016), tailored for this sensor. We also masked out RGI glaciers and water bodies (Pekel *et al* 2016).
2. We then identified snow-covered areas using a Normalized Difference Snow Index threshold value of 0.45 (Girona-Mata *et al* 2019). We determined the boundary of the snow-covered area and its elevation, ignoring boundary pixels adjacent to glaciers, water, clouds, and shadow (Girona-Mata *et al* 2019, Sasaki *et al* 2024).
3. We used the snow cover maps at 30 m resolution to derive monthly, seasonal and annual maps of snow cover frequency, defined as the ratio of snow observations to total observations, for each catchment for the 1999–2019, 1999–2009 and 2009–2019 study periods. We then used these results to determine the snow cover frequency distribution per elevation, based on the Advanced Land Observing Satellite (ALOS) World 3D (AW3D) 30 m digital elevation model (DEM, Tadono *et al* 2014). Monthly catchment snow line altitudes (SLA) were reconstructed using the mean elevation of the 0.5 frequency isoline of every available scene (figure 1(d)), similar to Krajčí *et al* (2014).
4. We used a second order harmonic function, a curve-fitting approach that is particularly suited to dealing with cyclical data such as seasonal changes, to fit the monthly SLAs for each catchment and each of the three study periods (Ronald Eastman *et al* 2009, Girona-Mata *et al* 2019) weighing the monthly values by the number of observations (figure 1(d)):

$$f(t) = a_0 + a_1 \cos(2\pi(\Phi_1 - t)/T) + a_2 \cos(2 \times 2\pi(\Phi_2 - t)/T)$$

where  $a_0$ ,  $a_1$  and  $a_2$  are the mean SLA, the first and second order SLA harmonic amplitudes, respectively. They were used to interpret the spatial and temporal variability of the SLA.  $\Phi_1$  and  $\Phi_2$  are phase parameters characterizing the timing of the SLA peaks and  $T$  the period. Such a regression can reproduce both a double and a single peak annual SLA, and the mean value and the two amplitudes, calculated directly, provide a readily accessible perspective of the spatial patterns

in snowline variations across the broad region (figure 1(d)). These second order harmonic functions were used to characterize the SLA seasonality and to compare between the three study periods. The monthly temporal aggregation was applied to reduce the influence of the limited number of available satellite images, especially in the first decade (SI figures 2–4). Furthermore, given the smoothing effect from the harmonic regression, using sub-monthly data has very little effect on our results.

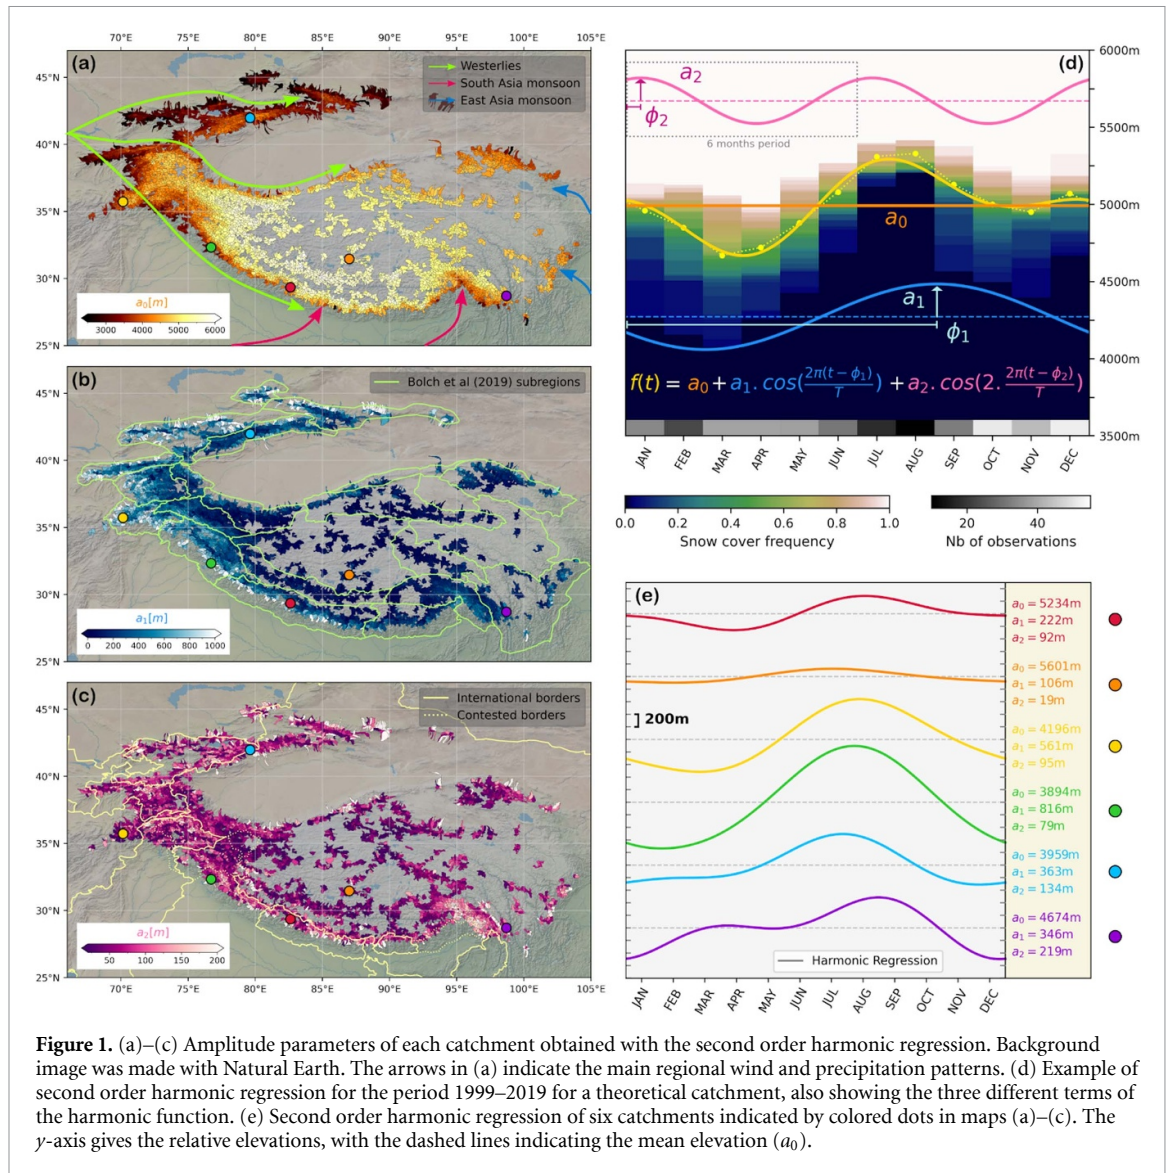

This method has identified snow-cover boundaries which correspond closely to manually-delineated snowlines from Landsat high-resolution multispectral imagery, while avoiding problematic deep shadows in regions characterized by steep topographies (Girona-Mata *et al* 2019). Despite differences in satellite sensors, data quality, resolution and processing between the Landsat and Sentinel-2 images, the method resulted in very close correspondence in SLA for overlapping periods at five catchments (Sasaki *et al* 2024), thus validating that the fusion of multiple data sources (from Landsat and Sentinel-2) has produced a consistent set of snowline observations.

## 2.2. Link with climate

Temperature, precipitation and snowfall (also referred to as solid precipitation) from ERA5-Land (Muñoz-Sabater *et al* 2021) were derived for each catchment. We consider ERA5-Land data as it has been applied to make assessments of climatological changes in HMA (e.g. Khanal *et al* 2023) or as forcing for glacier energy balance modeling (Arndt and Schneider 2023, Fugger *et al* 2024) and often is among the products with the best overall performance for those compared to ground stations (e.g. Hamm *et al* 2020, Kumar *et al* 2021, Nepal *et al* 2024), particularly for the analysis of monthly changes in temperature and precipitation. We used the minimum, maximum, mean annual, and mean June–July–August (JJA) temperature averaged over the three study periods. For precipitation and snowfall we used the mean annual, mean JJA, and mean March–April–May (MAM) values from ERA5-Land, from which we also derived solid fractions at the scale of the native grid resolution (~9 km).

In order to remove the elevation bias of the catchments, we applied an altitudinal normalization to all climatic variables (precipitation, snowfall, and temperature) following an approach similar to that presented by Machguth *et al* (2009) and using the AW3D 30 m DEM for distributed elevation data. This approach calculates a polynomial regression of order 4 between median elevation and median climatic variable (temperature, precipitation or snowfall) of each catchment, using 40 elevation quantiles to

**Figure 1.** (a)–(c) Amplitude parameters of each catchment obtained with the second order harmonic regression. Background image was made with Natural Earth. The arrows in (a) indicate the main regional wind and precipitation patterns. (d) Example of second order harmonic regression for the period 1999–2019 for a theoretical catchment, also showing the three different terms of the harmonic function. (e) Second order harmonic regression of six catchments indicated by colored dots in maps (a)–(c). The y-axis gives the relative elevations, with the dashed lines indicating the mean elevation ( $a_0$ ).

expose the underlying elevation effects (SI figure 5). The anomalies from this regression are then used to determine the catchment climatic variable values at a reference elevation of 4000 m (SI figure 5), effectively removing the elevation bias between catchments. We quantified the correlation between variables using the Spearman coefficient, using a threshold of  $\pm 0.85$  to consider the correlation significant. We used this definition to distinguish primary controls of SLA variation, which have a significant correlation with at least one amplitude parameter, from secondary controls, which have a significant correlation with at least one of the primary controls.

For the analysis of the variability in SLA in specific mountain ranges (Himalaya, Tien Shan and Kunlun-Altun Shan), we took into account the distance across each range and along each range. The distance across range was computed as the minimum length between the catchment center and the 1000 m (Himalaya)/1500 m (Tien Shan and Kunlun-Altun

Shan) altitude isoline. The distance along mountains was defined as the distance from the west end of the 1000 m/1500 m altitude isoline.

### 3. Results and discussion

#### 3.1. Spatial and seasonal variability of SLA across HMA

Our results show that the catchment mean annual SLA ( $a_0$ ) varies considerably across the region (figure 1(a)): mean annual SLAs are highest in the interior of the Tibetan Plateau, where they can exceed 5500 m asl (figures 1(a) and (e)), and considerably lower in the north of HMA (to 3000 m asl). Mean SLAs are also relatively lower around the periphery of each major mountain belt of the region, where orographic effects may lead to enhanced snowfall at intermediate elevations (Bookhagen and Burbank 2010, Wang *et al* 2020) despite considerably higher air temperatures.

The amplitude of the primary seasonal SLA harmonic ( $a_1$ ) also varies continuously across the region (figure 1(b)), but is anticorrelated to  $a_0$  ( $\rho = -0.99$ ), demonstrating that greater SLA seasonal variability occurs for catchments with lower annual-average snowlines. The greatest seasonal amplitudes are evident for the western and southern periphery catchments (up to 1000 m), while  $a_1$  is very low ( $<50$  m) for catchments within the interior of the Tibetan Plateau (figure 1(e)). SLAs present much stronger seasonal patterns in Western Himalaya and Hindu Kush with annual amplitudes from 500 m to 1000 m (figure 1(e)) and a clear single peak in seasonal SLA. For other catchments, SLA variations show a secondary peak, requiring a second harmonic ( $a_2$ ), for example in the Hengduan Shan ( $a_2 = 200$  m to 400 m) where spring and summer both provide substantial solid precipitation (e.g. Yang *et al* 2013, Jouberton *et al* 2022, figure 1(c)). For these domains, simple onset and duration snow phenologies provide inadequate description of snow-cover variability.

Our study introduces a much greater spatial detail and accuracy than past studies of snow spatial and seasonal variability (e.g. Smith and Bookhagen 2018, Ackroyd *et al* 2021, Tang *et al* 2022) due to the direct

use of the higher-resolution source data, against which MODIS observations are normally benchmarked (e.g. Rittger *et al* 2021). This higher resolution allows us to directly isolate the seasonal snowline elevation, rather than snow-covered area, and thus investigate the spatial variations of snow dynamics and their dependence on climate differences between distinct domains. This is particularly valuable due to the complex relationship with variables such as precipitation and its phase, which may be highly modulated by ongoing warming (Jennings *et al* 2018, Jouberton *et al* 2022) or the variable presence of the summer monsoon (Mölg *et al* 2014, Shaw *et al* 2022).

### 3.2. SLA variability is controlled by snowfall seasonal partitioning

We leverage catchment-specific results to investigate the climatological factors best explaining the spatial variations of SLA climatology in HMA. Our results highlight that metrics related to precipitation partitioning, rather than temperature itself, show the strongest correlation (0.8) with the spatial variations of SLA climatology (figure 2 and SI figure 6): the annual solid precipitation fraction and the summer

JJA and spring MAM fractions of annual solid precipitation. The annual solid precipitation fraction is inversely correlated with  $a_0$  (figure 2(d)); this is intuitive, as high solid precipitation fractions at the reference elevation promote lower-elevation snowlines.

Seasonal fraction of solid precipitation shows an even clearer association with the SLA climatology. The JJA fraction of annual snowfall is positively correlated ( $\rho = 0.99$ ) with  $a_0$ , while the MAM fraction of snowfall is negatively correlated ( $\rho = -0.88$ ) with  $a_0$  (figure 2 and SI figure 6). Catchments which receive their most extensive snowfall in warm summer months such as in the Central and Eastern Himalaya or parts of the Tibetan Plateau, linked to the monsoonal climate (e.g. Sakai and Fujita 2017), typically exhibit snow cover only at higher-elevations (high  $a_0$ ), and reduced SLA seasonality (low  $a_1$ , figure 3(b)). Catchments which receive extensive snowfall in spring months, on the other hand, accumulate snow at lower elevations (reducing  $a_0$ ) while also increasing the importance of seasonal snow depletion (higher  $a_1$ , figures 3(a) and (c)). In fact, these three elements highlight the interlinkages of precipitation and temperature seasonality to snow dynamics: although across catchments temperature itself is not directly related to SLA variations ( $\rho = 0.43$ ), the annual amplitude of temperature is positively correlated with  $a_1$  ( $\rho = 0.82$ ; SI figure 6). Indeed, the freezing line will vary with temperature, but this also implies that lower annual ranges

of temperature variation allow only high-elevation annual-average snowlines ( $a_0$ ).

The seasonal partitioning of snowfall and the solid fraction of precipitation can be identified as a common control of the spatial variability of SLA, despite its heterogeneity across HMA. These findings confirm that precipitation partitioning is the clearest driver for snow phenological differences across HMA (SI figures 6–10). This is particularly important given that differences in precipitation seasonality can sometimes have a much stronger role in affecting glaciers than differences in total annual precipitation amounts (Maussion *et al* 2014, Sakai and Fujita 2017, Smith and Bookhagen 2018, Jouberton *et al* 2022, Shaw *et al* 2022). Precipitation partitioning remains a major challenge for models and observations alike (e.g. Ding *et al* 2014, Jennings *et al* 2018, Jouberton *et al* 2022, Maina and Kumar 2023) and given forecasted warming in the 21st century, it will play an increasingly critical role in the presence of mountain snow cover and SLA in HMA (Li *et al* 2020, Lalande *et al* 2021, Collier *et al* 2024). Consequently, regional snow models should pay close attention to the interactions of temperature with precipitation for future simulations.

### 3.3. Influence of orography on SLA variability along the margins of HMA

We extend this analysis to examine the SLA variability across the principal topographic divides of HMA,

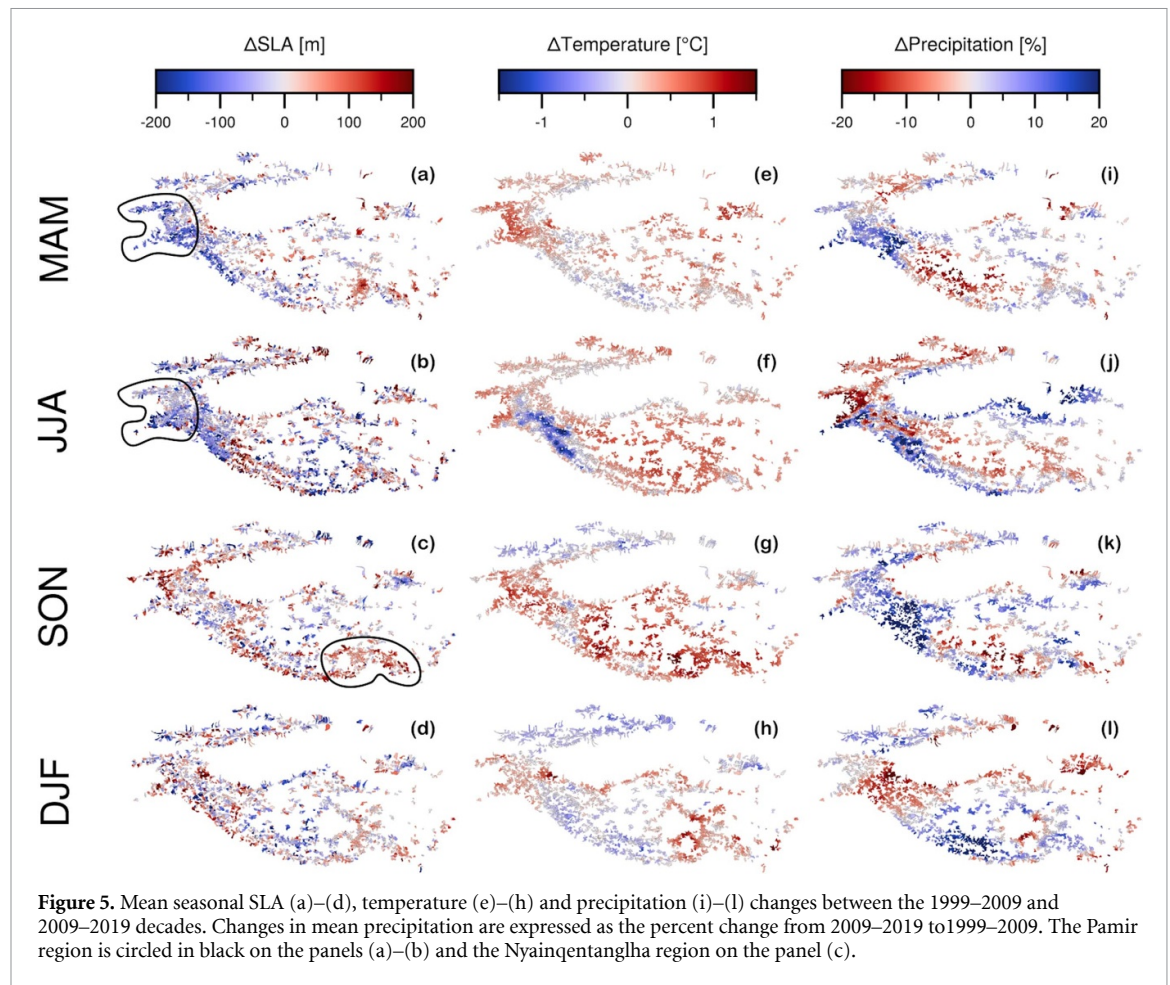

where climatic gradients are strongest, glaciers are most common, and topography modifies climatic patterns and resultant snow accumulation (Bookhagen and Burbank 2010, Maussion *et al* 2014, Potter *et al* 2018, Lalande *et al* 2023). The monsoonal-influence decreases across the Himalayas because of the orography: total precipitation and temperature decrease with elevation (figures 4(a)–(h)) and JJA/annual and MAM/annual snowfall show little variation (figures 4(d) and (h)). This relative change in the influence of the monsoon has a clear effect on a gradual increase of  $a_0$  and a decrease of  $a_1$ . Along mountains from west (0 km) to the mid-Himalayas (~1800 km—figure 4(i)), the south monsoonal influence increases and reaches a peak while westerlies become less dominant, reflecting an inverse relationship between JJA/annual and MAM/annual snowfall fractions (figures 4(d) and (h)). As a result,  $a_0$  increases from 3500 m to 5500 m and  $a_1$  decreases from 800 m to 200 m on this western portion of the along-mountains distance (figure 4(e)). Then, on the second portion (from 1800 km to 3000 km), the SLA parameters switch to the opposite trend, linked to a decreasing South but increasing East Asian monsoon influence. This local analysis highlights that the same principle controls are in play for the Hindu Kush–Karakoram–Himalaya range as across the broader region (figures 2 and 3(j–l)). Once again snowfall and precipitation partitioning metrics, highly influenced by macroscale climate patterns and their regional extents (e.g. the strength and intrusion of the summer monsoon), exert a clear control on both local and regional spatial variability of SLA (Bookhagen and Burbank 2010, Nash *et al* 2024). Similarly, for

the Tien Shan (SI figure 11) and Kunlun–Altun Shan (SI figure 12) mountain chains, we find again that snowfall (including seasonality) and precipitation partitioning metrics exhibit the strongest correlations with SLA phenology (SI text 1). Catchment temperature plays a secondary role in the Kunlun–Altun Shan, and shows no correlation in the Tien Shan.

### 3.4. Contrasting 21st century changes in SLA between the East and the West of HMA

Previous analyses have struggled to find clear trends due to the high interannual variability of snow metrics in HMA subregions (You *et al* 2020, Li *et al* 2022, Tang *et al* 2022, Ren *et al* 2024). Our comparison of the first two decades of SLA variations in the 21st century based on high resolution satellite imagery highlights several contrasting patterns of seasonal changes. The western regions of HMA (Pamir, Karakoram, Western Himalaya) have undergone increased snow coverage, expressed as seasonal SLA decrease, in spring and summer ( $-61 \pm 79$  m,  $-36 \pm 80$  m,  $-62 \pm 88$  m change in MAM averaged over the respective regions  $\pm$  the standard deviation,  $-32 \pm 100$  m,  $-29 \pm 96$  m,  $-48 \pm 158$  m in JJA, SI table 1). On the contrary, there is a widespread increase in SLA in autumn (September–October–November, SON) across the region, and especially Nyainqentanglha, Hengduan Shan and South-East Himalaya ( $+40 \pm 78$  m,  $+30 \pm 120$  m and  $+44 \pm 127$  m change in SON respectively, SI table 1 and figure 5). This corroborates previous observations that have indicated significant shortening of snow cover duration in Nyainqentanglha and Tien Shan, and increase in the Pamir, Karakoram and

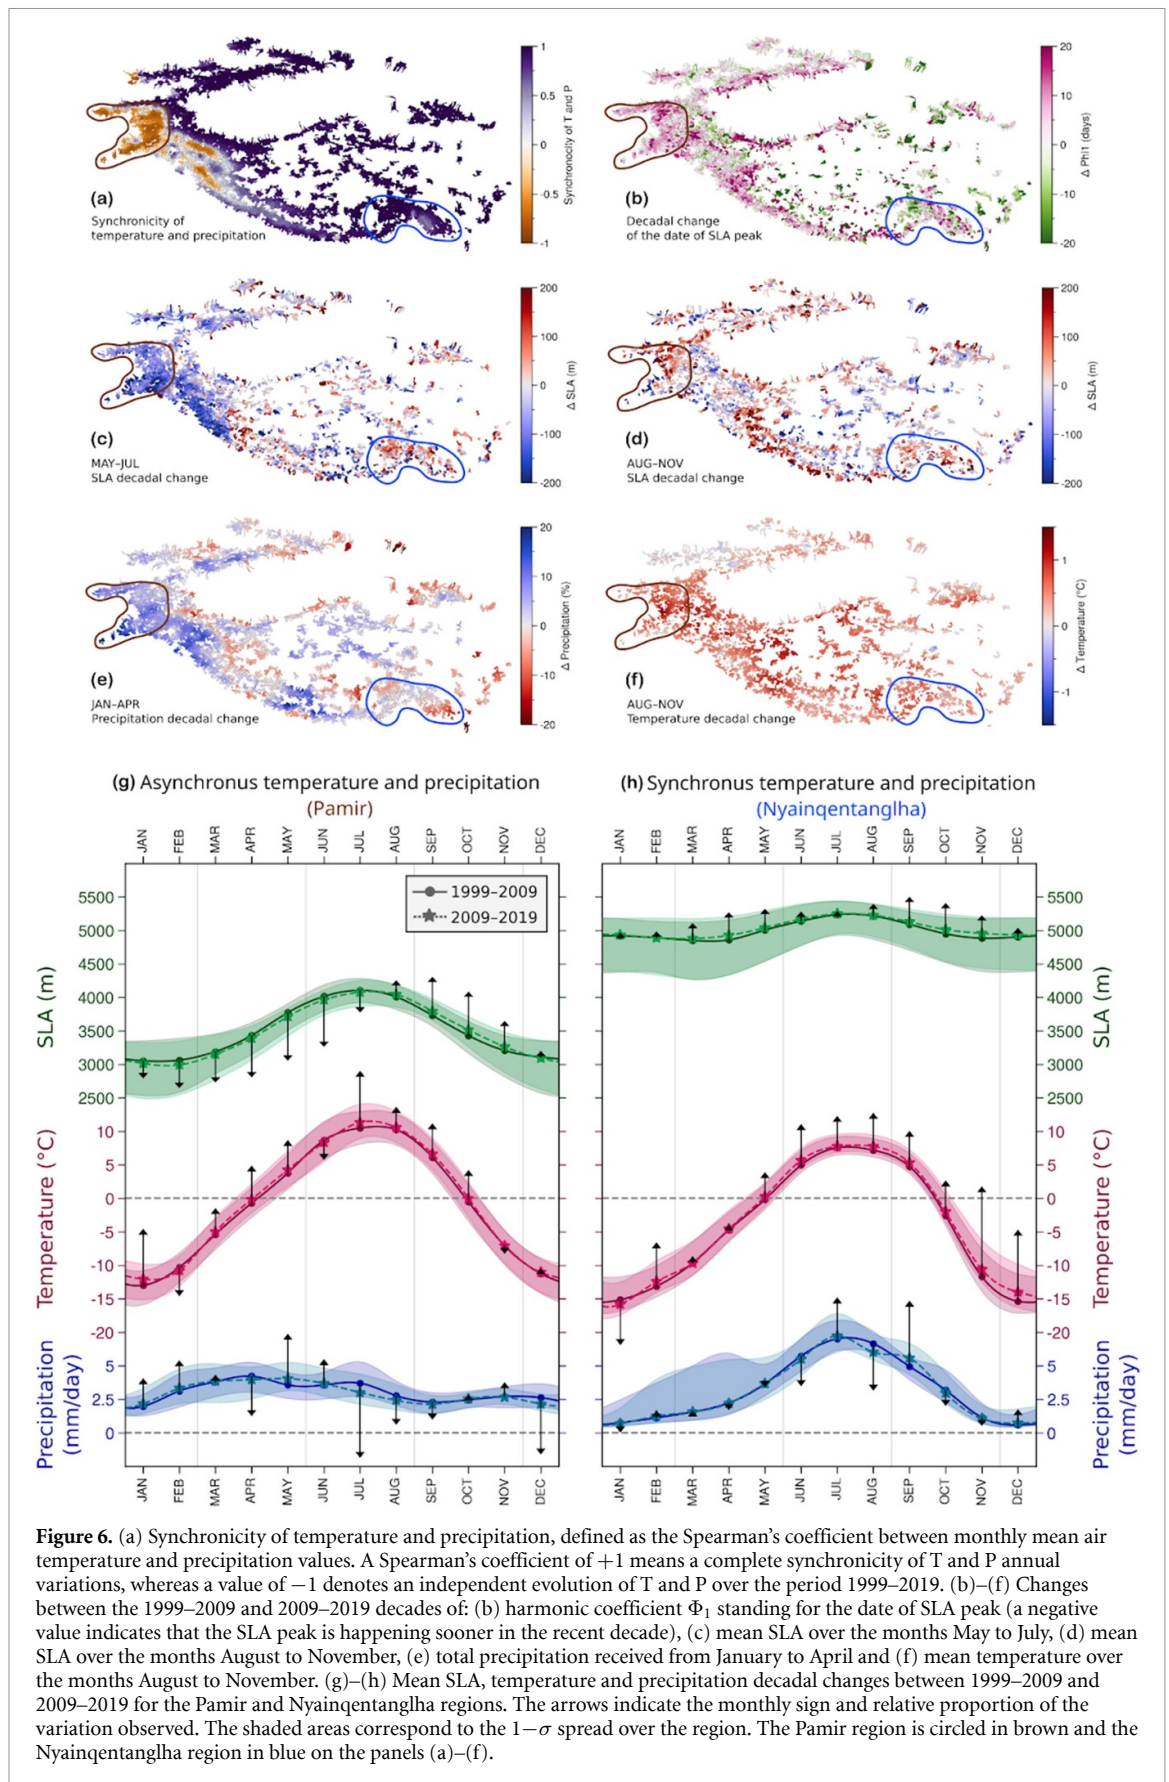

Western Himalaya regions (Tang *et al* 2022). Notably, both of these patterns are accompanied by a general increase in air temperature, especially in autumn and summer, except for parts of the Pamir (no temperature change) and Karakoram (cooling) regions in summer. The climatology suggests complex regional changes in seasonal precipitation, with precipitation increases in the Pamir and Karakoram in the spring and, more broadly, in the autumn (figure 5, Jiang *et al* 2023). Precipitation increases are evident along the Western and Central Himalayas, as well as along the Kunlun–Altun Shan, in the summer and autumn, whereas the Tibetan Plateau shows increased precipitation in autumn and winter. The Tien Shan exhibits a variety of precipitation patterns due to the complexity of local meteorology (e.g. Barandun *et al* 2021).

The temperature and precipitation patterns do not show a direct control on SLA changes (figure 5), but there is a clear correspondence between the spring and early summer snowline evolution (figure 6(c)) and the winter precipitation (figure 6(e)). For the western regions (Pamir and Karakoram especially), more snow in the winter results in lower SLA in the spring and early summer, as well as a later peak in SLA (figures 6(b) and (g)). In these regions the SLA

is not sensitive to increasing winter temperature as they remain far below the freezing line (figure 6(g)). There, the longer-lasting snowpack could, in fact, be partly responsible for the late spring and early summer decline in air temperature (figure 5(f), Wang *et al* 2018). In the eastern regions of South–East Himalaya and Nyainqentanglha, the increase in temperature particularly in spring and autumn renders the changes in total precipitation secondary, by controlling precipitation phase and snow cover retention, leading to a general increase in SLA particularly in these seasons (figure 6(h)). Despite a lower-elevation and longer-lasting snowpack in the West in the spring and early summer (figure 6(b)), the entire region undergoes rising SLA in the late summer and early autumn (figure 6(d)), indicating that these seasons are more sensitive to the rising air temperatures (figure 6(f)) than to the winter snowfall changes.

Our observed SLA changes correspond well to the geodetic mass balance and albedo patterns of glaciers observed over the period 2000–2020 (Hugonnet *et al* 2021, Ren *et al* 2024), indicating that glaciers undergo a similar response to regional climate changes. In particular, the albedo of glaciers has increased in the west in spring and summer, while it

has decreased everywhere else and in all other seasons (Ren *et al* 2024). Similarly, the Pamir, Karakoram and Kunlun regions demonstrated near-neutral glacier

mass balances during this period, while glaciers are losing mass extensively in all other regions (Hugonnet *et al* 2021). Two regional trends are therefore visible

in HMA during the 1999–2019 period: (1) In the west, higher winter snowfall results in a longer-lasting snowpack and lower SLA in spring and early summer (figures 5(a) and (b)) possibly leading to albedo driven and/or density driven (katabatic wind) summer cooling (figure 5(f)) which could have promoted a feedback toward a pattern of reduced mass loss (Farinotti *et al* 2020, Ren *et al* 2024). (2) In the east, a weakening summer monsoon combined with warming air temperature result in rising SLA and exacerbating declining glacier health (Miles *et al* 2021, Shaw *et al* 2022). This confirms the important link between the state of the spring and early summer snowpack and glacier health, although the generalized increase in summer and autumn temperatures limit this effect, leading to recent rising autumn SLA and glacier decline throughout the entire region (Hugonnet *et al* 2021, Ren *et al* 2024, Xie *et al* 2024).

### 3.5. Limitations

The greatest limitations of our approach come from the cloud cover preventing snowline identification in the optical satellite images, along with the variable frequency of image acquisitions throughout the study period. Although we expect these elements to have a limited influence on our analysis of the regional trends and drivers of SLA (Sasaki *et al* 2024), promising lines of research on sensor fusion (e.g. Rittger *et al* 2021), including with Synthetic Aperture Radar sensors, could reduce potential biases of future studies. Such studies will also benefit from longer records of earth observation data as well as from improved resolution and physics of climate reanalysis and atmospheric models (e.g. Collier *et al* 2024) that may further constrain the degree to which precipitation phase changes drive patterns of SLA response. Despite these limitations, the SLA patterns we quantified are robust and provide opportunities for both catchment and regional scale hydrological modeling through data assimilation (e.g. Metref *et al* 2023) and model validation (e.g. Buri *et al* 2023, Fugger *et al* 2024).

## 4. Conclusions

We calculated the SLA seasonality of all catchments in HMA for the period 1999–2019. Our results have shown a high spatial variability in the mean SLA and its seasonal patterns, with lower mean SLA in the southern and western periphery catchments, which is also where the yearly altitudinal amplitude of the snowline is the greatest. The catchment SLA is primarily controlled by the precipitation phase, in terms of the seasonal partitioning of precipitation and its phase rather than strictly with temperature itself, which highlights the influence of the different climatic regimes on the state of the snowpack and its evolution. In the monsoon-dominated catchments where most of the snowfall occurs during

the monsoon, the mean SLA is higher, while in the westerlies-dominated catchments, a high spring snowfall ratio leads to lower SLA and higher seasonal variability. These regional differences also lead to different responses to recent climatic changes. In the monsoon-dominated catchments, rises in temperature in the spring and autumn have led to a reduction in the snowfall partition and therefore rising SLA in these seasons. In the west, higher precipitation in winter and early spring has resulted in snow retention in spring and early summer. This precedes cooler air temperatures in summer, suggestive of a cooling effect from this longer-lasting snowpack, the combination of which could have contributed to maintaining glaciers in a near neutral mass balance in this region. However, the generalized rising temperatures limit this effect to spring and early summer and result in a region-wide increase in SLA in summer and autumn.

## Data availability statement

The data (catchment SLA and derived metrics) and codes that support the findings of this study are openly available at the following URL/DOI: <https://zenodo.org/records/15223344>.
